DEPARTMENT OF WATER AFFAIRS
DIVISION OF HYDROLOGICAL RESEARCH

EVALUATION OF DROUGHT CONDITIONS IN THE NORTHERN REGIONS OF SOUTH AFRICA.

By the Basic Research Section.

Rarely has a drought in South Africa been so widespread, so acute and in some regions so prolonged as that which was alleviated in most regions by soaking rains in April, 1965. More than two-thirds of the country experienced below-average rainfall in 1964 but whereas in the western regions the drought, while extreme, was preceded by one or more years of good rainfall, the drought in the northern regions persisted unremittingly for several years.

To assist those responsible for administering drought relief programmes, the intensity, duration and extent of the recent prolonged drought in the northern regions have been analysed and compared with those of previous severe droughts.

Ideally analysis of drought should be based on the daily balance between the quantity of available water in the soil and the water requirements of a crop or the natural vegetation. However, this requires information on a wide range of factors such as rainfall intensity, infiltration capacity, soil moisture characteristics and evapotranspiration rate, concerning some of which very little is known. The present analysis has therefore been based solely on monthly rainfall data. As none of the methods encountered in the literature on drought analysis was considered to be entirely appropriate, a new method had to be evolved. The analysis covered more than 150 rainfall stations with records varying in length from 30 to 80 years, and was carried out with the aid of an electronic computer.

METHOD.

There are 4 main components to the drought analysis, viz.:-

- a. calculation of various criteria such as effective monthly rainfall, mean monthly and annual rainfall and certain parameters used to establish the start and termination of drought;
- b. the test to determine the start of a drought;
- c. the test to determine the end of a drought;
- d. analysis of the duration and intensity of drought periods identified by tests (b) and (c).

A. BASIC PREMISES AND CALCULATION OF DROUGHT CRITERIA AND PARAMETERS.

The analysis is based on 4 premises, viz.:-

1./.....

- 2 -

1. Farming in any region is adapted to the prevailing climatic pattern; thus in a region of pronounced seasonal variation in rainfall the most important months agriculturally are those with the highest mean rainfall.
2. If there is some seasonal variation in mean monthly rainfall so that on the average some months are drier than others, it implies that seasonal drought of a certain intensity and duration is a normal feature of the climate of the region to which farming has become adapted and should therefore be excluded from an assessment of damaging droughts.
3. Likewise as the rainfall of any month varies from year to year, it is assumed that farming is adjusted to the average variability, and that only rainfall deficits exceeding the average deficit of any month should be included in an evaluation of harmful drought.
4. It is assumed
 - (i) that the benefit to vegetation of above-average rainfall persists for some time beyond the month in which the rain fell, due to storage of moisture in the soil, and conversely
 - (ii) that recovery of vegetation after drought is not immediate, the harmful effect of a drought persisting for some time after adequate rain has fallen.

The same empirical formula has been used to calculate the carry-over effect in both cases and is based on the first premise, in that the weighting factor relates to the mean rainfall of the month receiving the carry-over. In other words it is assumed that the carry-forward effect - beneficial or detrimental as the case may be - will be greater in the agriculturally more important months of high average rainfall than in normally drier months. The recorded rainfall of any month plus the quantity (positive or negative) carried forward from previous months is termed the effective rainfall.

The mean rainfall for each of the twelve months of the year having been calculated and summated to yield the mean annual rainfall, a weighting factor was calculated according to the following formula to enable effective rainfall to be calculated:-

$$W(I) = \frac{1}{10} \left\{ 1 + \frac{M(I)}{\frac{1}{12} (MAP)} \right\} \dots \dots \dots \quad (1)$$

where

$W(I)$ is the weighting factor for month I,
 $M(I)$ is the mean rainfall for month I,
MAP is the mean annual rainfall.

$W(I)$ varied from little more than $\frac{1}{10}$ to about $\frac{4}{10}$ where the ratio $(MI)/\frac{1}{12} MAP$ equalled about 3.

Thereupon the effective rainfall for each month of a station record was calculated by allowing for the carry-over effect of a surplus or deficiency of rainfall in the preceding month. Starting at the first month of the record, the mean rainfall for that month, say January, was subtracted from the measured rainfall, a positive difference indicating that excess rainfall in that month whereas a negative difference indicated that the rainfall of that month was deficient. The difference, whether/....

whether positive or negative, was weighted with the factor pertaining to the following month, the product with its sign being then added algebraically to the measured rainfall of the following month, the sum thus representing the effective rainfall of that month (in this case February). From this amended value of rainfall for February was subtracted the mean for that month, the difference being weighted by the factor of the following month (in this case March) and carried over to that month. The process was continued so as to obtain a full record of effective monthly rainfall.

Next the difference between the effective rainfall of a month and the mean rainfall for that month was calculated for all months, most of the later testing for start and termination of drought being based on these differences.

A new parameter was calculated at this stage, namely the mean monthly deficit for each of the twelve months, this being the mean of all negative differences between effective rainfall and mean rainfall for a particular month throughout the record; the deficit was deemed to be zero when a positive difference occurred, these zero deficits also being included in the calculation of mean monthly deficit. In this way the mean monthly deficit (MMD) for each of the 12 months was calculated, summation yielding the mean annual deficit (MAD).

Another set of parameters necessary for later tests of start and termination of drought was the value of highest mean monthly rainfall, the sum of the two highest values of mean monthly rainfall, the sum of the three highest monthly means and so on up to the sum of the twelve highest values of mean monthly rainfall which is of course equivalent to the mean annual rainfall.

B. TEST USED TO DETERMINE START OF DROUGHT.

It is not always possible merely by inspecting a rainfall record to decide in which month a drought commences, due to the occurrence intermittently of months of above-average rainfall within a drought period. Consequently a method had to be devised of deciding on balance whether or not a month of deficient rainfall constitutes the start of a drought, should it be followed by months of both above- and below-average rainfall.

The test is based on a comparison of the sum of the negative differences x from the point in time at which the test commences, with a sliding scale of 12 values calculated by interpolating linearly between the maximum value of mean monthly rainfall (MMMR) and the mean annual deficit (MAD). A monthly increment x is thus obtained from the formula

The first value on the sliding scale is equal to M_{MMR} , being the maximum deficit that can occur in a single month (when no rain falls in the month which normally receives most rain). The second value on the sliding scale is obtained by adding $1x$ to M_{MMR} , the third by adding $2x$, and so on up to $M_{MMR} + 11x$ which is equivalent to MAD.

The test for start of drought was conducted as follows:

Firstly it was assumed that no drought prevailed just prior to the start of the available rainfall record.

The /.....

* Hereinafter the term "difference" refers to the difference between the effective rainfall of a month and the mean rainfall for that month of the year.

- 4 -

The difference between the rainfall of the first month of the record and the mean for that month of the year was inspected; if it was positive, obviously it did not signify the start of a potential drought and the differences of the succeeding months were inspected until a month with a negative difference was found, such a month representing the start of a potential drought. The absolute value of the negative difference was compared with the first value of the sliding scale, viz. MMMR and if the latter was equalled (a rare possibility) a drought was deemed to have started. However if MMMR was not equalled the difference of the next month was inspected and if also negative was added to the negative difference of the first month (to which the test for start of drought was being applied) and compared with the second value on the sliding scale, namely MMMR + 1x; if this criterion was exceeded by the absolute value of the two deficits combined, a drought was deemed to have started from the first month. In this manner the absolute value of the sum of all rainfall deficits occurring from the first month over a period of a year was tested sequentially against the 12 values of the sliding scale. If at any time the absolute value of all deficits occurring from, and including, the first month up to, and including, the i th. month exceeded the value $MMMR + x (i-1)$, a drought was deemed to have started from the first month. However, simultaneously with this sequential testing the algebraic sum of all differences from the first month of test was found and if at any time during the 11 tests the algebraic sum became positive (that is, rainfall surpluses exceed rainfall deficits - relative to the mean - over the period concerned) the potential drought was considered to have ended. Testing for start of drought then recommenced at the next month with a negative difference after that month from which the preceding test was carried out.

The outcome of this 12 month test could be one of the following:-

- (i) A drought start was found, in which case testing for termination commenced from the first month with a positive difference following the month in which the drought started.
- (ii) A potential drought was found and terminated, a contingency which has already been discussed.
- (iii) The start of a drought was not found, nor was the potential drought terminated; in this case testing was resumed from the first month with a negative difference following the month from which the previous inconclusive test had been carried out.

Where the start of a drought was not found, as in (ii) and (iii), testing recommenced repeatedly until one of the tests for start of drought was satisfied.

C. TEST TO DETERMINE THE TERMINATION OF DROUGHT.

In the first instance the test was applied to the period following the first month with a positive difference occurring after the start of a drought.

- (i) A precondition to be satisfied was that at least one of the two months immediately following the initial month with a positive difference after the start of a drought should also have a positive difference. If this condition was met

then/.....

- 5 -

then the initial month qualified for further testing for termination of drought, otherwise the conditional test recommenced from the second month with a positive difference.

- (ii) The precondition having been satisfied, tests (ii) and (iii) were applied simultaneously. Test (ii) was designed to establish whether the spell of above-average rainfall constituted merely an interruption or suspension of drought rather than its termination, the drought being resumed thereafter.

It entailed simply adding algebraically all differences from and including that of the first month of the test; if the sum became negative before a termination condition had been satisfied by test (iii), then the drought was deemed to have been only temporarily interrupted. Testing for termination thereupon recommenced anew at the first month with a positive difference following that from which the previous unsuccessful test had proceeded.

- (iii) This test - carried out simultaneously with, and subject to, test (ii) - comprised 10 sequential tests. In the first test the actual rainfall during the three months following and including the month from which the test started was compared with the sum of the three highest values of mean monthly rainfall; if the actual rainfall was the higher, the drought was considered to have been terminated, but if not then the sum of the first four months was compared with the sum of the four highest values of mean monthly rainfall, and so on - should the drought not yet have been terminated - up to a comparison of the sum of the rainfall of the twelve months following and including the month from which the test commenced, with the mean annual rainfall. By this stage either the drought had been terminated - in which case it was deemed to have ended in the month from which the multiple test had been initiated - or drought conditions had been resumed after a temporary interruption, in which case the algebraic sum of the differences would have become negative as described in test (ii).

Once a termination had occurred, testing for start of the next drought commenced at the first month with a negative difference following the month in which the drought ended.

D. STUDY OF DATA IN PERIODS IDENTIFIED AS DROUGHTS.

To enable the various droughts identified within a long term rainfall record to be compared, the following data were recorded in respect of each:-

1. The month in which the drought started.
2. The month by which the drought had ended.
3. The duration of the drought, in months.
4. The sum of all negative differences - that is, deficits below the mean - occurring during the span of a drought, in inches.

5./.....

- 6 -

5. The sum of mean monthly deficits in inches over a period identical to that of the drought, the notation $\frac{\Sigma}{S} MMD$ being used to indicate the sum of mean monthly deficits from the start to the termination of the drought. This could be compared with the sum of actual deficits occurring during the drought period (see 3) to provide a measure of the relative intensity of the drought in terms of the mean drought, but this is considered to be inferior to the method described in 8 below.
6. The sum throughout the drought period of deficits in excess of the mean deficit of each month, termed the total excess deficit.
7. The number of months during which excess deficits occurred during a drought.
8. An index Y of drought intensity, obtained by dividing the total excess deficit (see 6) by $\frac{\Sigma}{S} MMD$ (see 5).
9. A weighted drought severity index YD, being the product of the severity index Y (see 8) and the duration of the drought (see 3). This is the key unit, making it possible to compare directly droughts differing in both intensity and duration, which have occurred in a particular rainfall record.
10. The rainfall occurring during the drought expressed as a percentage of the sum of mean monthly rainfall over the period of the drought.
11. The rainfall occurring during the preceding wet period (that is, which intervened since the previous drought) expressed as a percentage of the sum of the mean monthly rainfall over that period.

The mean monthly rainfall and deficits have all been recorded in inches, being the unit used throughout.

RESULTS.

To suit the convenience of those responsible for allocating financial relief to farmers, the rainfall records used in the analysis were grouped according to the Agro-economic Regions within, or near, which they were located, and averaged so as to obtain a single representative rainfall record for each Region. Although the disposition of the rainfall stations is such that their average does not necessarily correspond accurately with the true average rainfall over a Region, such a record is nevertheless quite suitable for comparing the relative intensity of droughts which have occurred from time to time in any Region. As the station records did not all commence in the same year, some of the early averaged data were discarded, only years of record incorporating at least 75% of the total number of stations falling in a Region being accepted. Drought data pertaining to each Agro-economic Region are listed in Table 1 to 19, the distribution of rainfall stations, and their identifying numbers, being shown in Figure 1.

Table 20/.....

- 7 -

Table 20 lists the individual rainfall stations, the monthly rainfall of which was averaged for each Agro-economic Region as shown, together with the name, latitude and longitude of each station.

It will be noted that in the following Regions the most recent drought ^{*} was more severe (judged by the Y x D index) than any which occurred previously within the period of record:-

CENTRAL TRANSVAAL IRRIGATION AREAS:-

A1 Western Transvaal (Western region)

CATTLE GRAZING AREAS:-

M5 Pienaars River and Olifants River Area (Western region)
 M6/1 North Western Transvaal (Rooiberg Blouberg Area)
 M6/2 North Western Transvaal (North Western Waterberg)
 M6/3 North Western Transvaal (Rustenburg Thabazimbi Area)
 M7 Agter Soutpansberg.

To permit of more detailed study of variations in drought duration and intensity within the regions, the record of each station was analysed individually. Listed in Table 21 for each rainfall station are data pertaining to the most recent drought. By way of comparison the five worst droughts in the record (based on the Y x D index) together with the number of years in the record, are also recorded for each station. Whenever the current drought was one of the five worst droughts in the record, only the four worst droughts apart from the current one were listed. In all cases, for each station, the droughts were assigned order numbers, and for each listed drought the order number was also listed, so that in cases where the current drought was not one of the five worst droughts in a record, it can still be seen from Table 21 how many times a worse drought occurred.

It will be noted that in most instances the recent drought is shown as continuing beyond March 1965, the date at which the study terminated. This reflects what the effect of the drought carry-over would have been even if monthly rainfall in the ensuing 12 months had exceeded the average by 10%. This assumption was made for lack of real figures. It must be stressed therefore that in most cases the actual drought might not have been broken yet, April 1965 being merely the date at which the study was terminated.

According/.....

^{*}

The term "most recent" or "current" or "present" drought refers not only to a continuous dry period preceding March 1965, but also to cases where a drought was terminated in 1964 (usually in November) and started again in January 1965. In the latter cases the drought index and duration of the two separate droughts were combined and distinguished by an asterisk.

- 8 -

According to the theory, the Y x D index is not only comparable in time for one station or region, but is also comparable from station to station and from area to area. Keeping this in mind the Y x D indexes for the current drought were plotted on a map for each of the Agro-economic regions. It is evident from this map, shown in Figure 2, that the drought stricken territory can be divided broadly into five areas, all differing in the degree to which they have been affected. The drought condition of region M6/1 was based on the average rainfall of stations representative of only the eastern part of the region and consequently reflects only the drought condition of that part, this being the reason why the western part of M6/1 was classified under the area of most severe drought. These five regions, each consisting of one or more agro-economic regions, are shown in Figure 2, by means of different shading. The Y x D index for each Agro-economic region (in rounded thousands) as well as the duration in months, is also shown.

The division of the country into Agro-economic Regions is based on a classification of regions of the same agricultural potentiality, which is a function of topography, temperature, soil type, vegetation and rainfall. Thus, although related to some, rainfall is not the only characteristic of an Agro-economic Region and a drought investigation (based only on rainfall data) will therefore not conform exactly to the boundaries of these regions. As expected, the drought indexes (see Table 21) of individual stations in a region will show discrepancies, especially near the boundaries where transition lines are not easy to demarcate.

Table 22 shows the five groups of areas, with the regions they comprise together with the Y x D index and duration of the current drought for each region. The areas have been arranged in descending order of magnitude of severity of the current drought, as judged by the Y x D index.
